Keywords: All-terrain rovers, traction control, wheel-slippage reduction.

SUMMARY. Mobile robots are increasingly being employed in challenging outdoor applications including search and rescue for disaster recovery, construction, mining, agriculture, military and planetary exploration. In this kind of robotic applications, the accuracy and robustness of the motion control system is greatly affected by the occurrence of undesired dynamics effects such as wheel slippage. In this paper a cross-coupled controller is presented that can be integrated with 4-wheel-drive/4-wheel-steer robots to optimize the wheel motors’ control algorithm and reduce synchronization errors that would otherwise result in wheel slip with conventional controllers. Experimental results, obtained with an all-terrain rover operating outdoor, are presented to validate this approach showing its effectiveness in reducing slippage and vehicle posture errors.

1 INTRODUCTION

The motion accuracy of mobile robots driving across undulating terrains is strictly connected with the ability of avoiding wheel slippage. As the vehicle travels on irregular terrain, its suspension system conforms to terrain topography, possibly resulting in different loading profiles applied to the drive wheels. If each wheel is controlled independently in a closed-loop manner, this may result in one wheel accelerating while another wheel slowing down to reach its speed set point, thus promoting slippage and tendency to sideslip. The problem is exacerbated in so-called over-constrained robots, i.e., featuring more independent motors than degrees of motion. A notable example are the NASA’s Mars rovers [1], which are equipped with six independently controlled drive motors and six independently controlled steering motors. Other examples of mobile robots with over-constrained drive systems are the six-wheeled Shrimp [2], the Nomad Arctic traverse robot developed at Carnegie Mellon University [3], wheeled snake-type robots like the ones developed by Hirose et al. [4], and hybrid leg/wheel systems [5]. One method for reducing the occurrence of slippage in over-constrained vehicle is the Cross-Coupled Control (CCC) strategy that was proposed by Borenstein and Koren [6] for a two-wheel differential drive vehicle.

This paper develops and experimentally validates the CCC idea for the general case of a rover outfitted with four independently steered and driven wheels, as introduced in [7]. The system continuously compares the actual encoder readings from all four wheels and issues corrective commands to the motors to decelerate the motors that are faster and speed up the motors that are slower than the others. In conventional mobile robots controllers, each drive loop receives no information about the others, and any disturbance in one loop causes an error that is corrected only by this loop, while the other loops carry on as before. Cross-coupled control is used to remedy this problem by sharing the feedback information of all control loops. The overall effect is that the wheel velocities are matched more tightly even in the presence of internal and external disturbances. It should be also noted that the proposed control strategy does not require any additional sensors other than wheel encoders and steer potentiometers that are commonly available in most robots. The proposed CCC algorithm is validated in the field using the all-terrain rover Dune, built at the Applied Mechanics Laboratory of the Università del Salento. Dune, shown in Figure 1, is an independently controlled four-wheel-
drive/four-wheel steer mobile robot, also featuring a rocker-type suspension system. This architecture provides a high degree of mobility, allowing the robot to safely traverse rocks over one and half its wheel diameter and to perform specific maneuvers such as crab and turn-on the spot motion. Its operational speed ranges from 2 to 40 cm/s. The sensor suite is composed of optical encoders and potentiometers, to measure, respectively, the wheel angular velocities and the wheel steering angles. A fiber optic gyro is also used to provide the actual rate-of-turn of the robot during experiments.

One other important benefit of the CCC system should be mentioned. As the rover travels over highly irregular terrain, it is possible the case that one wheel is “in the air”. If each of the wheels is independently powered by a motor, then the free-spinning wheel and motor do not contribute torque to propel the vehicle forward. As a result, the vehicle may stall on high-resistance surfaces, such as soft sand. The CCC partially mitigates this problem by increasing the speed of the “stuck” wheel, as the system attempts to equalize the speed of the remaining cross-coupled wheels.

The remainder of the paper is organized as follows. Basic principles of vehicle kinematics are recalled in Section 2. Section 3 describes the proposed motion controller showing all the technical and mathematical details. In Section 4, the CCC strategy is validated showing the experimental results obtained from the rover Dune in presence of external disturbances applied to a single wheel and when the robot travels on an agricultural terrain following a linear and turning path. The CCC performance are also compared against the conventional approach demonstrating the benefits of the proposed approach. Section 5 concludes this paper.

2 KINEMATIC STEERING

Consider a four-wheel-drive/steer robot that is turning counter-clockwise, as shown in Figure 2, under the assumption of planar motion. Typical travel speeds for all-terrain rovers are low and the kinematic condition that the perpendicular lines to each wheel meet at one point must be applied in order to guarantee slip-free turning. A kinematic (or Ackermann) steering model can be reasonably assumed where the velocities of the centers of all wheels lie in their midplane, i.e. the sideslip angles are vanishingly small. The intersection point $O$ is the turning center or instantaneous center of rotation of the vehicle. It may change from moment to moment; for straight-line motion, the
radius from $O$ to each wheel is of infinite length, whereas it is null for turn-on-the spot motion. The rover mass center $G$ turns on a circular path with radius $R$, and linear and angular velocity vector $\vec{V}$ and $\vec{\omega}$, respectively. The distance between the front and the rear axle is the wheelbase $l$, whereas the distance between the wheels of the same axle is called the track $t$. Each wheel has a linear velocity vector $\vec{V}_i$ and a steering angle $\delta_i$, which is measured between the longitudinal direction of the vehicle and the steering direction of the wheel. The vector projection of the speed vector $\vec{V}_i$ onto the $y$-axis of the vehicle is called lateral velocity component $\vec{V}_{y,i}$ and it is marked in red in Figure 2. The concept of lateral velocity component will be useful later in the paper to define the cross-coupled control strategy during turning maneuvers. In this work, a symmetric four-wheel steering rover is considered where the front and rear wheels steer opposite to each other equally. This configuration is also usually referred to as a negative four wheel steering. According to the notation used in this paper, vector quantities are distinguished from scalar ones by using a right-pointing arrow above their names.

3 CROSS-COUPLLED MOTION CONTROL

Mobile robots can be seen as multi-axis drive servomechanisms. Disturbances that affect one control loop may differ from disturbances that affect the other loops. Even if each axis is equipped with a high performance tracking controller, the error in one axis will affect the motion of the whole system. If this phenomenon is overlooked and each axis is controlled independently, it will most likely lead to poor motion accuracy. The problem is exacerbated in over-constrained vehicles, where any momentary mismatch between wheel velocities with respect to the vehicle kinematic model will result in wheels “fighting” each other with consequent ill-effects, including increase in power consumption and errors in the odometry-based position estimation [8], and reduction in traction and climbing ability [9]. For instance, during a simple forward-backward motion all the wheels have to
run at exact same speed to avoid slippage, any momentary mismatch between wheel velocities will force the wheels to skid or slip unpredictably. In order to achieve a coordination control, a cross-coupled control approach can be applied where the whole multi-axis system is considered as a single system. Compensations are calculated by taking into account the mutual influences to match more tightly the different axes and consequently reduce the error in the global motion control. The CCC continuously compares the wheel encoder pulses of a robot to slow down the motor that is faster and speed up the motor that is slower than the others. The overall effect of this approach is that the wheel velocities are matched more tightly according to the correct kinematic behavior of the robot. The proposed cross-coupled approach differentiates between straight and turning motion. When the rover follows a straight path, the average longitudinal velocity is estimated and the deviation of a given wheel from this average value is used to adjust the associated set point in order to gain speed synchronization. During turning maneuvers, the single speed set points are corrected based on the discrepancy with a so-defined mean absolute lateral velocity. Details of how the CCC handles these two types of motion are presented in the remainder of this section.

3.1 Linear Motion

Figure 3 shows a block diagram with the implementation of the cross-coupled control for one wheel of the rover. The scheme is the same for the remaining wheels and it is not reported. Based on the estimation of the wheel velocities \( V_i \) \((i = 1, \ldots, 4)\) by encoders, the average vehicle speed can be calculated by

\[
V_{avg} = \frac{\sum_{i=1}^{4} V_i}{4} \quad (1)
\]

The deviation of the \( i \)-th wheel from the average value, \( e_{CCC,i} = V_i - V_{avg} \), is used as input error to a proportional-integral (PI) controller that estimates the required change in the commanded velocity set point \( \Delta V_i \) relative to the nominal velocity set point \( V_{ref,i} \) according to the following equation:

\[
V_i = V_{ref,i} - \Delta V_i \quad (2)
\]

If wheel \( i \) travels faster than the average vehicle speed, then the CCC module reduces the velocity set point of this wheel in order to synchronize more tightly the velocity of all wheels.

3.2 Turning Motion

During turning maneuvers, each wheel travels with a velocity proportional to the distance from the instantaneous center of rotation, \( i.e. \), the inner wheels are slower than the outer wheels, as shown in Figure 2. However, the projection of wheel velocities along the \( y \)-axis of the vehicle must be equal in absolute value in order to ensure a correct kinematic behavior. This can be proved via graphical velocity analysis of the rover, as illustrated in Figure 4. The vector relationships between the velocities of the front and rear wheel pairs are respectively

\[
\vec{V}_1 = \vec{V}_2 + \vec{\omega} \times (1 - 2) \quad (3)
\]
\[
\vec{V}_3 = \vec{V}_4 + \vec{\omega} \times (3 - 4) \quad (4)
\]

where \( \vec{\omega} \) is the rate of turn of the rover and the geometric point \( I = 1, \ldots, 4 \) refers to the center of the associated wheel. If Equations (3) and (4) are projected over the \( y \)-axis of the rover, it gets

\[
V_{y,f} = V_1 \cdot \sin \delta_1 = V_2 \cdot \sin \delta_2 \quad (5)
\]
Figure 3: Block diagram of a cross-coupled control loop for the $i$-th wheel of the rover during linear motion. The conventional part of the control loop is denoted by a solid black line. The CCC part is outlined by a red dashed line.

$$V_{y,r} = V_3 \cdot \sin \delta_3 = V_4 \cdot \sin \delta_4$$

(6)

Under the assumption of symmetric steering, the magnitude of the lateral velocity component has to be equal for the front and rear wheel pairs, i.e., $V_{y,f} = V_{y,r} = V_y$. Note, however, that the direction of the lateral velocity component for the front wheels is opposite to that of the rear wheels.

Figure 5 shows the typical block diagram with the implementation of the cross-coupled control for one wheel of the rover. The lateral velocity component for wheel $i$ can be obtained based on the estimation of its linear velocity $V_i$ by encoder, and steer angle $\delta_i$ by potentiometer

$$V_{y,i} = V_i \cdot \sin \| \delta_i \|$$

(7)

Since we are interested in the magnitude of $V_{y,i}$, the absolute value of $\delta_i$ is considered. Then, the mean absolute lateral velocity can be obtained by

$$V_{y,avg} = \frac{\sum_{i=1}^{4} V_{y,i}}{4}$$

(8)

and the deviation of the $i$-th wheel from $V_{y,avg}$, $e_{CCC,i} = V_{y,i} - V_{y,avg}$, is used as input error to the CCC correction module following the same rationale described for straight-line motion. The new velocity set point is obtained again using Equation (2). This approach can be applied to any turning maneuver including turning on the spot. It should be also noted that the CCC does not provide any correction for the steering angles. This choice is motivated by the observation that the traction dynamics is significantly faster than the steering one. Therefore, traction and steering control are tackled separately with decoupled control loops.

Another alternative solution may be implemented based on the concept of angular velocity $\omega$ of the robot. In principle, during a turning maneuver all points of the vehicle must rotate with the same angular velocity around the instantaneous center of rotation $O$, as shown in Figure 2. For example, the angular velocity pertaining to wheel $i$ can be expressed as
Figure 4: Graphical analysis of the wheel velocities of a rover with symmetric steering. All wheels admit equal lateral velocity components in magnitude. Direction of the lateral velocity components of the front wheel pair is opposite to that of the rear pair.

\[ \omega_i = \frac{V_i}{R_i} \]  

(9)

where \( R_i \) is the distance from \( O \) to wheel \( i \). In general, \( R_i \) can be obtained respectively for the inner and outer wheels as

\[ R_i = \frac{R - \frac{t}{2}}{\cos \delta_i} \]  

(10)

\[ R_i = \frac{R + \frac{t}{2}}{\cos \delta_i} \]  

(11)

Based on Equation(9), the angular velocity of each wheel can be estimated through the measurement of the linear velocity by encoder and steer angle by potentiometer. By averaging the single wheel angular velocities, the robot turning rate can be drawn. When the wheel angular velocity of a given wheel is compared with the robot average value, an input error to the CCC correction module can be obtained for this wheel.

The two proposed implementations for turning motion were tested in simulation showing similar performance. However, the latter approach requires prior knowledge of the geometry of the robot (i.e., the robot track \( t \)) that is not always known or easy to measure depending on the operating conditions of the rover. Therefore, the former implementation is adopted in the rest of the paper.

4 EXPERIMENTAL RESULTS

In this section, experimental results are presented to validate the proposed cross-coupled control approach. The system was integrated with the rover Dune (see Figure 1) and demonstrated in a rural environment at a Università del Salento’s test facility comprising relatively even agricultural

6
terrain with sparse low grass and rocks of small-medium size. During the experiments, the rover was remotely driven by a human operator as the onboard computer gathered encoder, potentiometer and gyroscope information for subsequent off-line analysis. The main idea behind the cross-coupled approach can be explained with a preliminary experiment where the rover was commanded to drive straight forward as braking torques were applied to one of the wheels, i.e., front-right Wheel 2, in order to introduce random disturbances into its control loop. As shown in Figure 6(a), under conventional controller (CC) large differences in the wheel velocities were produced with consequent, undesired increase in the amount of slippage. This effect is due to the lack of communication between the control loops. The conventional control was implemented as a standard Proportional-Integral-Differential (PID) controller, as customary in many robotic platforms. The application of the cross-coupled control strategy improved the rover’s behavior as shown in Figure 6(b). In contrast to conventional control, the cross-coupled controller compares all control loops instant by instant (a sampling interval of $T = 0.01 \text{ s}$ was used) decreasing or increasing the wheel velocities that are higher or lower than the average vehicle travel speed. The overall result is a better synchronization of all wheel velocities with a consequent minimization of slippage.

Different types of experiments were conducted on Dune to evaluate the performance of the CCC method with respect to the conventional control. Two main performance metrics were used to quantitatively evaluate the system: the orientation error and the tracking error. The orientation error is defined as

$$\Delta \theta = \frac{\Delta d_r - \Delta d_l}{t}$$

(12)

where $\Delta d_r$ and $\Delta d_l$ are the right and left side longitudinal displacement as measured by encoders in the sampling period and $t$ the track of the vehicle. It has been shown to play a fundamental role in dead-reckoning accuracy since it grows with the traveled distance. The tracking error can be defined for wheel $i$ as

$$\Delta s_i = \left( \frac{V_i}{V_{avg}} - 1 \right) \times 100\%$$

(13)
Figure 6: Change in wheel angular velocities in presence of external disturbances applied to front-right Wheel 2. (a) Conventional control: The control loops do not share information resulting in Wheel 2 rotating faster or slower than the other wheels. (b) Cross-coupled control: By sharing information between the control loops, all wheel velocities are matched more tightly.

For example, if one wheel spins at high angular velocity without the equivalent translatory progression of the rover, i.e., \( V_t \geq V_{avg} \), a positive value for the tracking error results. \( \Delta s_i \) can be interpreted as a measure of the effectiveness of the control system in avoiding slippage.

4.1 Single Primitives of Motion

Tests were first performed along a 5-meter straight path with a constant travel speed of 10 cm/s. Six runs with each control method were performed. Figure 7 shows a comparison of the typical orientation error growth using the CC (marked by a solid grey line) and the CCC (denoted by a solid black line) controllers in a sample run. The encoder-derived measurement (solid line) is compared with the actual heading change (dashed line), provided by a fiber-optic gyro aligned along the vertical axis of the vehicle that is used as the ground truth in this type of experiments. In order to gain an indication of the error accumulation, the final orientation error is considered as obtained from the odometry at the end of each run. The mean final orientation error and standard deviation in all experiments resulted in 3.8 ± 0.8 deg under CC, and 0.7 ± 0.2 deg using CCC. It is apparent from
Figure 7: Comparison of cross-coupled control with conventional control: Change in the orientation error during a single 5-meter straight path test on agricultural terrain (V = 10 cm/s). (a) Black solid line: Encoder-derived orientation error using the CCC. Black dashed line: Gyro-derived ground truth. (b) Black solid line: Encoder-derived orientation error using the CC. Black dashed line: Gyro-derived ground truth.

These results indicate that using a conventional PID controller the orientation error continuously increases, while, under cross-coupled control, a correction signal is generated when discrepancies between the wheel velocities are detected, thus reducing the rover orientation error. In order to evaluate the effectiveness of reducing slippage using the CCC, the mean tracking error was estimated for each run. Then, the average over the six experiments was calculated along with its statistical spread. Using the CC, the average wheel slip was $0.93 \pm 0.12\%$, with Wheel 1 experiencing the highest value of $1.17 \pm 0.15\%$. The application of the CCC greatly reduced the percentage of wheel slip to only $0.23 \pm 0.02\%$ on average with an upper bound of $0.29 \pm 0.03\%$ for Wheel 1.

A second set of experiments was performed driving the rover with a constant linear velocity of 5 cm/s along a circular path with a turning radius of 5-meter (i.e., rate-of-turn $\omega = 0.05$ rad/s) on agricultural terrain. Figure 8 shows the odometry-derived path for a sample run. The commanded path is denoted by a grey solid line, the path derived by the odometry system using the CCC is marked with a black solid line, and the CC is denoted by a dashed black line. Six similar runs with each control method were performed. The final orientation error with respect to the actual heading change of 90 deg was estimated for each run. It resulted in an average of $12.10 \pm 2.10$ deg using CC, and in $1.10 \pm 0.21$ deg on average when the CCC was applied. Wheel slip was obtained as an average value over the six runs. Under CC, the average tracking error resulted in $2.21 \pm 0.40\%$. The application of the CCC improved the rover performance by reducing the percentage of wheel slip to only $0.55 \pm 0.01\%$ on average. The cross-coupled approach again outperformed the conventional control. It is apparent from these results that the CCC module is indeed effective in minimizing the difference in wheel velocities of the rover in both straight and turning maneuvers.

4.2 Closed-loop Experiments

Experiments were performed along a closed path to test the improvement in motion accuracy using the CCC method. Dune traveled autonomously along a preprogrammed, near rectangular path
over agricultural terrain. In order to perform long duration tests, each run consisted of three uninterrupted loops, resulting in a total travel distance of about 37 m, and a total of 1,080 degrees of turning per run. The speed in all runs was 10 cm/s, and the rover did not stop before turning. A set of multiple runs was performed consisting of six runs in clockwise (CW) and six runs in counterclockwise (CCW) direction. For each test, Dune started at a marked location and ended back at the initial starting position. The discrepancy between the actual stopping position and the starting position, measured with a tape measure, is the so-called “return position error”. The average absolute positioning errors $E_x$ and $E_y$ can be obtained respectively as $E_x = \frac{1}{m} \sum \| x_r \|$, and $E_y = \frac{1}{m} \sum \| y_r \|$, where $x_r$ and $y_r$ are the return position error measured along $x$- and $y$-direction, respectively, and $m = 6$ the number of runs. Finally, an absolute error can be estimated as $E = (E_x^2 + E_y^2)^{0.5}$. Figure 9 shows the return position error for each run in graphical form. Using the CCC approach, the average absolute positioning errors resulted in $E_x = 17.25$ cm and $E_y = 19.41$ cm, respectively, with an absolute error $E_{CCC} = (17.25, 19.41) = 25.96$ cm corresponding to the 0.70% of the total path length of 37 meter associated with each run. Under conventional control the errors grew up to $E_x =$ 20.43 cm and $E_y =$ 35.23 cm with a global error $E_{CC} =$ (20.43, 35.23) = 40.72 cm corresponding to the 1.10% of the path length. The experimental results show that the CCC approach leads to a substantial improvement in motion accuracy than conventional methods.

5 CONCLUSIONS

In this paper, a cross-coupled control approach was described to improve motion accuracy of all-terrain rovers with independently steered and driven wheels. It aims to optimize the motors’ control algorithm of the robot to reduce synchronization errors that would otherwise result in wheel slip with conventional controllers. Experimental results obtained using a test platform, operating outdoor in a rural environment, validated the system that could be successfully applied to enhance the degree of mobility and autonomy of all-terrain robots.
